6.8 Shortest Paths

Shortest Paths

Shortest path problem. Given a directed graph $G = (V, E)$, with edge weights c_{vw} , find shortest path from node s to node t .

↖ allow negative weights

Ex. Nodes represent agents in a financial setting and c_{vw} is cost of transaction in which we buy from agent v and sell immediately to w .

Shortest Paths: Failed Attempts

Dijkstra. Can fail if negative edge costs.

Re-weighting. Adding a constant to every edge weight can fail.

Shortest Paths: Negative Cost Cycles

Negative cost cycle.

$$\ell(W) = \sum_{e \in W} \ell_e < 0$$

Observation. If some path from s to t contains a negative cost cycle, there does not exist a shortest s - t path; otherwise, there exists one that is simple.

Shortest Paths: Optimal Substructure

Def. $OPT(i, v)$ = length of shortest v - t path P using at most i edges.

- Case 1: P uses at most $i-1$ edges.
 - $OPT(i, v) = OPT(i-1, v)$
- Case 2: P uses exactly i edges.
 - if (v, w) is the first edge, then OPT uses (v, w) , and then selects best w - t path using at most $i-1$ edges

$$OPT(i, v) = \begin{cases} 0 & \text{if } i = 0 \text{ and } v = t \\ \infty & \text{if } i = 0 \text{ and } v \neq t \\ \min \left\{ OPT(i-1, v), \min_{(v,w) \in E} \{OPT(i-1, w) + \ell_{vw}\} \right\} & \text{if } i > 0 \end{cases}$$

Remark. By previous observation, if no negative cycles, then $OPT(n-1, v)$ = length of shortest v - t path.

Shortest Paths: Optimal Substructure

$\text{OPT}(i, v) :=$ the min cost of a v - t path using at most i edges.

- If the path P uses at most $i-1$ edges, then $\text{OPT}(i, v) = \text{OPT}(i-1, v)$.
- If the path P uses i edges, and the first edge is (v, w) , then $\text{OPT}(i, v) = c_{vw} + \text{OPT}(i-1, w)$.

$$\text{OPT}(i, v) = \min(\text{OPT}(i-1, v), \min_{w \in V} (\text{OPT}(i-1, w) + c_{vw}))$$

Shortest Paths: Implementation

```
Shortest-Path( $G, t$ ) {  
  foreach node  $v \in V$   
     $M[0, v] \leftarrow \infty$   
   $M[0, t] \leftarrow 0$   
  
  for  $i = 1$  to  $n-1$   
    foreach node  $v \in V$   
       $M[i, v] \leftarrow M[i-1, v]$   
      foreach edge  $(v, w) \in E$   
         $M[i, v] \leftarrow \min \{ M[i, v], M[i-1, w] + c_{vw} \}$   
}
```

Analysis. $\Theta(mn)$ time, $\Theta(n^2)$ space.

Finding the shortest paths. Maintain a "successor" for each table entry.

Shortest Paths: Bellman-Ford Example

	0	1	2	3	4	5	<i>i</i>
<i>t</i>	0	0	0	0	0	0	
<i>a</i>	∞	-3	-3	-4	-6	-6	
<i>b</i>	∞	∞	0	-2	-2	-2	
<i>c</i>	∞	3	3	3	3	3	
<i>d</i>	∞	4	3	3	2	0	
<i>e</i>	∞	2	0	0	0	0	
<i>v</i>							

Order of subproblems being solved: $1 \rightarrow 2 \rightarrow 3 \rightarrow 4 \rightarrow 5$

The shortest path from node *d* to *t* is updated four times, as it changes from *d-t*, to *d-a-t*, to *d-a-b-e-t*, and finally to *d-a-b-e-c-t*

Shortest Paths: Practical Improvements

Practical improvements.

- Maintain only one array $M[v]$ = shortest v-t path that we have found so far.
- No need to check edges of the form (v, w) unless $M[w]$ changed in previous iteration.

Theorem. Throughout the algorithm, $M[v]$ is length of some v-t path, and after i rounds of updates, the value $M[v]$ is no larger than the length of shortest v-t path using $\leq i$ edges.

Overall impact.

- Memory: $O(m + n)$.
- Running time: $O(mn)$ worst case, but substantially faster in practice.

Bellman-Ford: Efficient Implementation

```
Push-Based-Shortest-Path( $G, s, t$ ) {  
  foreach node  $v \in V$  {  
     $M[v] \leftarrow \infty$   
    successor[ $v$ ]  $\leftarrow \phi$   
  }  
  
   $M[t] = 0$   
  for  $i = 1$  to  $n-1$  {  
    foreach node  $w \in V$  {  
      if ( $M[w]$  has been updated in previous iteration) {  
        foreach node  $v$  such that  $(v, w) \in E$  {  
          if ( $M[v] > M[w] + c_{vw}$ ) {  
             $M[v] \leftarrow M[w] + c_{vw}$   
            successor[ $v$ ]  $\leftarrow w$   
          }  
        }  
      }  
    }  
    If no  $M[w]$  value changed in iteration  $i$ , stop.  
  }  
}
```

6.9 Distance Vector Protocol

Distance Vector Protocol

Communication network.

- Node \approx router.
- Edge \approx direct communication link.
- Cost of edge \approx delay on link. \leftarrow naturally nonnegative, but Bellman-Ford used anyway!

Dijkstra's algorithm. Requires global information of network.

Bellman-Ford. Uses only local knowledge of neighboring nodes.

Synchronization. We don't expect routers to run in lockstep. The order in which each `foreach` loop executes is not important. Moreover, algorithm still converges even if updates are asynchronous.

Distance Vector Protocol

Distance vector protocol.

- Each router maintains a vector of shortest path lengths to every other node (distances) and the first hop on each path (directions).
- Algorithm: each router performs n separate computations, one for each potential destination node.
- "Routing by rumor."

Ex. RIP, Xerox XNS RIP, Novell's IPX RIP, Cisco's IGRP, DEC's DNA Phase IV, AppleTalk's RTMP.

Caveat. Edge costs may **change** during algorithm (or fail completely).

Path Vector Protocols

Link state routing.

- Each router also stores the entire path.
- Based on Dijkstra's algorithm.
- Avoids "counting-to-infinity" problem and related difficulties.
- Requires significantly more storage.

↙ not just the distance and first hop

Ex. Border Gateway Protocol (BGP), Open Shortest Path First (OSPF).

6.10 Negative Cycles in a Graph

*Sec 6.10 of textbook

Questions:

- How do we decide if a graph contains a negative cycle?
- How do we actually find a negative cycle in a graph that contains one?

Detecting Negative Cycles

Lemma. If $\text{OPT}(n,v) = \text{OPT}(n-1,v)$ for all v , then no negative cycles.

Pf. Bellman-Ford algorithm.

Lemma. If $\text{OPT}(n,v) < \text{OPT}(n-1,v)$ for some node v , then (any) shortest path from v to t contains a cycle W . Moreover W has negative cost.

Pf. (by contradiction)

- Since $\text{OPT}(n,v) < \text{OPT}(n-1,v)$, we know P has exactly n edges.
- By pigeonhole principle, P must contain a directed cycle W .
- Deleting W yields a v - t path with $< n$ edges $\Rightarrow W$ has negative cost.

Detecting Negative Cycles

Theorem. Can detect negative cost cycle in $O(mn)$ time.

- Add new node t and connect all nodes to t with 0-cost edge.
- Check if $\text{OPT}(n, v) = \text{OPT}(n-1, v)$ for all nodes v .
 - if yes, then no negative cycles
 - if no, then extract cycle from shortest path from v to t

Detecting Negative Cycles: Application

Currency conversion. Given n currencies and exchange rates between pairs of currencies, is there an arbitrage opportunity?

套利

Remark. Fastest algorithm very valuable!

Detecting Negative Cycles: Summary

Bellman-Ford. $O(mn)$ time, $O(m + n)$ space.

- Run Bellman-Ford for n iterations (instead of $n-1$).
- Upon termination, Bellman-Ford successor variables trace a negative cycle if one exists.
- See p. 304 for improved version and early termination rule.
